I. INTRODUCTION

In earlier work funded by the Treasury Department [2,3], I attempted to estimate service lives and depreciation patterns of capital goods employed in manufacturing industries which on average best accounted for observed fluctuations in capital spending. I have referred to these as the service lives and depreciation patterns revealed or indicated by investment behavior.

This study explores some of the implications of my previous findings.^{1/} By applying the revealed services lives and depreciation patterns to capital expenditures in each industry, I have prepared estimates of annual depreciation flows which are not only consistent over time, but which also reflect actual service lives and actual losses in efficiency of capital goods as they age. Two variants of these depreciations flows are considered, the first based on historical cost of assets and the second on current, or replacement, cost of assets. Section II details the assumptions and algebraic formulas appropriate to each measure. The estimates are presented in Section III, where they are compared with the Bureau of Economic Analysis (BEA) data on capital consumption allowances. Section III also compares profit estimates based on my measures of depreciation with BEA profit estimates.

I have drawn a distinction in my previous papers between replacement requirements and depreciation. Replacement requirements measure the amount of real capital expenditures needed to maintain the productive capacity of the existing stock of capital, whereas depreciation reflects the decline in value of the existing stock of capital over the

accounting period. I have shown that replacement requirements and depreciation are the same only under conditions of constant geometric decay of productive capacity of capital goods and constant prices. Since constant geometric decay of productive capacity was not revealed by investment behavior in any manufacturing industries, and since prices do change over time, the empirical relation between replacement requirements and depreciation is worth exploring. Section IV presents my estimates of replacement requirements valued at current prices and compares them with both my series and the BEA series on depreciation.

In applying my revealed service lives and depreciation patterns to capital expenditures, it is possible to estimate not only annual flows of depreciation but also the value of equipment and structures in existence at the end of each year - what I shall call the "book value" of those assets. Taking the ratio of my estimate of profits (including net interest) to the average of book value of assets at the beginning and end of the year, I arrive at estimates of the rate of return on capital which embody consistent measurements of depreciation and book values - not only consistent over time, but consistent with my findings on service lives and patterns of loss of efficiency of capital goods. These new estimates of rates of return in manufacturing industries are presented in Section V.

II. HISTORICAL AND CURRENT-COST CONCEPTS OF ECONOMIC DEPRECIATION

A. The Historical-Cost Concept. In my initial study, I showed how a capacity depreciation pattern, depicting the loss of efficiency of a capital good as it ages, can be translated into a pattern of economic depreciation, depicting the loss in value of the capital good as it ages. To illustrate, consider an asset whose service life is three years. Let d_j be the loss of productive capacity of the asset in year j of its life relative to its efficiency when new. Suppose that the asset adds X units to real net output (net of material costs, labor, and other costs) and that the output's selling price, P , remains constant through time. The asset will then give rise to the following stream of net money returns.

<u>Year of Service Life</u>	<u>Net Money Return</u>
1	PX
2	$PX(1-d_1)$
3	$PX(1-d_1-d_2)$

The value of the asset at the end of each year is given by the present value of the stream of net money returns from that year to the end of the service life. If r is the discount rate (assumed constant over time), then for the asset being considered we have,

$$C_0 = \frac{PX}{1+r} + \frac{PX(1-d_1)}{(1+r)^2} + \frac{PX(1-d_1-d_2)}{(1+r)^3} \quad (1)$$

$$z_1 = \frac{PX(1-d_1)}{1+r} \quad \frac{PX(1-d_1-d_2)}{(1+r)^2} \quad (2)$$

$$z_2 = \frac{PX(1-d_1-d_2)}{1+r} \quad (3)$$

$$z_3 = 0 , \quad (4)$$

where c_0 is the original cost of the asset, z_1 is the value of the asset at the end of its first year of service, and so forth. Depreciation each year, d_j , defined as the loss in value of the asset, is given by

$$d_1 = c_0 - z_1 \quad (5)$$

$$d_2 = z_1 - z_2 \quad (6)$$

$$d_3 = z_2 - z_3. \quad (7)$$

What property do these measures of depreciation possess? In each year of the asset's life, it generates a certain amount of money receipts. The problem of depreciation accounting is to decompose these receipts into two components, one of which we call income, the other depreciation. If we define income as the portion of receipts which could be consumed (or withdrawn for some other purpose) and still leave the owner with the same real wealth at the end of the year as he possessed at the beginning of the year, then the depreciation method proposed is the appropriate one, provided that the price of a comparable new asset is not changing over time.

To establish that this proposition is correct, let us examine the situation in the first year of the asset's life. Suppose we denote income in year 1, as income was defined above, by y_1 . The owner's nominal wealth at the beginning of year 1 is simply c_0 , and his real wealth is one capital good. If the price of new capital goods of this type is constant through time, then we require that the owner's wealth at the

end of year 1 be C_0 , so that his real wealth will not have changed. He will, of course, have a used asset worth Z_1 at that time, and he will have $PX - Y_1$ in cash. Thus, if his wealth at the end of year 1 is to be C_0 , then we must have

$$PX - Y_1 + Z_1 = C_0 . \quad (8)$$

But $PX - Y_1$ is what we would identify as depreciation in year 1, D_1 , so that

$$D_1 = C_0 - Z_1 . \quad (9)$$

Receipts in the second year are composed of two flows: (1) the net money return generated by the asset, $PX(1-d_1)$, and (2) interest on depreciation set aside in year 1, rD_1 . Also, the owner's wealth at the end of year 2 is composed of two items: (1) the two-year old asset worth Z_2 , and (2) the amount of cash set aside for depreciation in year 1, D_1 . Again assuming that the price of a new capital good similar to the used one has not changed, we require that the owner's wealth at the end of year 2 be C_0 . Thus,

$$PX(1-d_1) + rD_1 - Y_2 + Z_2 + D_1 = C_0 \quad (10)$$

Since D_2 is $PX(1-d_1) + rD_1 - Y_2$, that is, total receipts minus income, we have

$$D_2 = C_0 - Z_2 - D_1 = C_0 - Z_2 - C_0 + Z_1 = Z_1 - Z_2 . \quad (11)$$

Similar reasoning would lead to the conclusion that $D_3 = Z_2 - Z_3$.

With depreciation in each year defined by these expressions, it can easily be shown that income in each year of the asset's life is the same and equal to rC_0 .

Thus, under the assumption of constant prices, the calculation of depreciation is straightforward. For our purposes, it is convenient to normalize the depreciation flows in the above example on the initial value of the asset. This gives us a set of parameters v_j , defined as

$$v_1 = \frac{c_0 - z_1}{c_0} \quad (12)$$

$$v_2 = \frac{z_1 - z_2}{c_0} \quad (13)$$

$$v_3 = \frac{z_2 - z_3}{c_0} , \quad (14)$$

which characterize the pattern of economic depreciation on the asset. In other words, the v_j depict the pattern of economic depreciation on an asset costing one dollar when new. Depreciation in each year and the value of the asset at the end of each year can then be expressed in terms of the original value of the asset:

$$d_1 = v_1 c_0 \quad z_1 = (1-v_1)c_0 \quad (15)$$

$$d_2 = v_2 c_0 \quad z_2 = (1-v_1-v_2)c_0 \quad (16)$$

$$d_3 = v_3 c_0 \quad z_3 = 0 . \quad (17)$$

This approach, based as it is on the assumption of constant prices, is rather unrealistic. Its implementation results in depreciation measures reflecting the historical, or original, cost of assets. In times of changing prices, historical-cost depreciation will be incorrect in the sense that the measure of income associated with it will not properly indicate how much of current receipts can be consumed and still

leave real wealth intact. Nonetheless, the simplicity of historical-cost depreciation and its conceptual similarity to tax accounting practices in the U.S. are desirable features.

To explain how this approach is applied in the present study, I employ the following notation:

I_{tk}^e = equipment expenditures in current prices in year t for industry k.

I_{tk}^s = structures expenditures in current prices in year t for industry k.

v_{ik}^e = loss in value of one dollar of equipment used by industry k in the i-th year after the equipment is acquired.

v_{ik}^s = loss in value of one dollar of structures used by industry k in the i-th year after the structures are acquired.

D_{tk}^e = total economic depreciation (loss in value) of all equipment used by industry k in year t.

D_{tk}^s = total economic depreciation of all structures used by industry k in year t.

D_{tk} = total economic depreciation of all equipment and structures used by industry k in year t.

The v 's, which indicate the patterns of economic depreciation on equipment and structures, are derived from the service lives and capacity depreciation patterns revealed by investment behavior, according to the procedure described above. The index k runs from 1 to 21, covering the 21 two-digit manufacturing industries in the Standard Industrial Classification. We then have

$$D_{tk}^e = \sum_{i=1}^{n_k^e} v_{ik}^e I_{t-i,k}^e \quad (18)$$

$$D_{tk}^s = \sum_{i=1}^{n_k^s} v_{ik}^s I_{t-i,k}^s \quad (19)$$

$$D_{tk} = D_{tk}^e + D_{tk}^s, \quad (20)$$

where n_k^e and n_k^s are, respectively, the service lives of equipment and structures indicated by investment behavior in industry k. Summing the D_{tk} over all 21 industries, we have an estimate of the flow of economic depreciation for total manufacturing in year t.

B. The Current-Cost Concept. Capital goods prices commonly change over time, raising serious difficulties in the measurement of depreciation and income. Any approach to depreciation measurement under circumstances of changing prices is necessarily arbitrary. We can formulate a set of assumptions and examine their implications, but it must be recognized that a different, and perhaps equally plausible, set of assumptions may lead to different results.

I shall make the following assumptions for the purposes of this study:

- (a) Changes in capital goods prices result solely from changes in prices of the outputs which they produce.
- (b) Changes in product prices are entirely unforeseen by the owners of capital goods.
- (c) The value of a capital good is equal to the present value of the expected stream of net money returns which it will produce.

(d) Product price expectations are completely inelastic.

That is, actual or potential owners of capital goods expect present prices of products to prevail into the indefinite future.

We shall develop the implications of these assumptions in a fashion which parallels the discussion in the previous section.

Suppose an individual owns a new capital good for which he paid c_0 dollars. The capital good has a three-year life, and its capacity depreciation in year j is d_j . The current price of output produced by this piece of capital is P_0 , which the owner expects to remain at this level. Thus, at the time of purchase, the owner anticipates that the value of this asset at the end of each year will be

$$c_0 = \frac{P_0 X}{1+r} + \frac{P_0 X(1-d_1)}{(1+r)^2} + \frac{P_0 X(1-d_1-d_2)}{(1+r)^3} \quad (21)$$

$$z_1^0 = \frac{P_0 X(1-d_1)}{1+r} + \frac{P_0 X(1-d_1-d_2)}{(1+r)^2} \quad (22)$$

$$z_2^0 = \frac{P_0 X(1-d_1-d_2)}{1+r} . \quad (23)$$

We now place a superscript "0" on z_1 and z_2 to indicate that they are anticipations held at the end of year 0. The actual value of the asset at the end of year 1 may not be z_1^0 , however, owing to an unforeseen change in the product price. If the product price turns out to be P_1 , in year 1, and if participants in the capital-goods market revise their expectations and believe that the future output price will be P_1 , then the value of the asset at the end of year 1 will be

$$z_1^1 = \frac{P_1 X (1-d_1)}{1+r} + \frac{P_1 X (1-d_1-d_2)}{(1+r)^2} \neq z_1^0 . \quad (24)$$

Thus, an unexpected change has occurred in the value of the capital good. Note also that a new capital good of the same type should sell at the end of year 1 at the price

$$C_1 = \frac{P_1 X}{1+r} + \frac{P_1 X (1-d_1)}{(1+r)^2} + \frac{P_1 X (1-d_1-d_2)}{(1+r)^3} . \quad (25)$$

If the owner of the capital good is to have the same real wealth (that is, one capital good) at the end of period 1 as at the end of period 0, his nominal wealth at the end of period 1 must be C_1 . His nominal income in year 1 is then implicitly defined by

$$P_1 X - Y_1 + z_1^1 = C_1 , \quad (26)$$

so depreciation in year 1 is

$$D_1 = C_1 - z_1^1 . \quad (27)$$

However, given the definition of the v_j in the previous section, we see that $z_1^1 = (1-v_1)C_1$ and

$$D_1 = v_1 C_1 = v_1 C_0 \left(\frac{C_1}{C_0} \right) . \quad (28)$$

The expression $v_1 C_0$ is the historical-cost depreciation in the first year on an asset purchased at the end of year 0. The factor (C_1/C_0) inflates this historical-cost depreciation to the level of capital goods prices prevailing at the end of period 1. I shall refer to such a depreciation measure as current-cost depreciation. The form derived here for the first year is in accord with a frequently heard policy proposal, namely, that firms should be permitted to adjust their historical-cost depreciation to reflect the level of current capital goods prices.

However, moving on to the second year, the situation is no longer so simple.

Suppose that the price of output changes in year 2 to P_2 and that, as a consequence, the price of a new capital good of the original type changes to C_2 at the end of year 2. Income in year 2 is implicitly defined by

$$P_2 X(1-d_1) + rD_1 - Y_2 + D_1 + z_2^2 = C_2 , \quad (29)$$

where z_2^2 is the market value of the two-year old asset and $z_2^2 \neq z_2^0$.

In particular, we have

$$z_2^2 = \frac{P_2 X(1-d_1-d_2)}{1+r} . \quad (30)$$

Depreciation in year 2 is then

$$D_2 = C_2 - D_1 - z_2^2 . \quad (31)$$

Again recalling the definition of the v_j , we have $z_2^2 = (1-v_1-v_2)C_2$

so that

$$\begin{aligned} D_2 &= (v_1+v_2)C_2 - v_1 C_0 \left(\frac{C_1}{C_0}\right) \\ &= v_2 C_2 + v_1 C_2 - v_1 C_0 \left(\frac{C_1}{C_0}\right) \\ &= v_2 C_0 \left(\frac{C_2}{C_0}\right) + [v_1 C_0 \left(\frac{C_2}{C_0}\right) - v_1 C_0 \left(\frac{C_1}{C_0}\right)] . \end{aligned} \quad (32)$$

Depreciation in the second year contains two elements. The first is the historical-cost depreciation on a two-year old asset revalued to reflect the price of a new capital good at the end of year two. The second is the first-year historical-cost depreciation valued at year 2's

capital goods price less the same historical-cost depreciation valued at year 1's capital goods price. This second element can be interpreted as an adjustment factor for the first-year depreciation, taking account of the change in the price of a new capital good between years 1 and 2.

By the same logic, depreciation in the third year can be shown to be

$$D_3 = v_3 C_0 \left(\frac{C_3}{C_0} \right) + [v_2 C_0 \left(\frac{C_3}{C_0} \right) - v_2 C_0 \left(\frac{C_2}{C_0} \right)] \\ + [v_1 C_0 \left(\frac{C_3}{C_0} \right) - v_1 C_0 \left(\frac{C_2}{C_0} \right)] . \quad (33)$$

The three components of D_3 may be interpreted as follows. The first is the third-year historical-cost depreciation revalued to the current price level. The second is the adjustment of second-year historical-cost depreciation required to revalue it to the current price level. And the third is the adjustment of first-year historical-cost depreciation required to revalue it to the current price level, recognizing that it had already been adjusted to year 2's price level in calculating depreciation in year 2. The concept of current-cost depreciation implied by our assumptions does not merely involve the revaluation of historical-cost depreciation in each year to reflect the current price of a new capital good. It involves this revaluation plus continued adjustments of past depreciation estimates to place them on a current-cost basis. Depreciation over the service life, according to this approach, sums to C_3 , which is the cost of purchasing a new capital good of the original type at the end of year 3 (the end of the service life).^{2/} In other words, the present concept of current-cost depreciation leads to a stream of depreciation charges which sum to the eventual replacement cost of the asset.

To show how this approach is implemented in the current study, I shall use the notation given in the preceding section. Additionally, C_{tk}^e can be defined as the price index for new equipment purchased by industry k in year t, and C_{tk}^s as the price index for new structures purchased by industry k in year t. We then have the following expressions for current-cost depreciation:

$$D_{tk}^e = \sum_{i=1}^{n_k^e} v_{ik}^e I_{t-i,k}^e \frac{C_{tk}^e}{C_{t-i,k}^e} + \sum_{i=1}^{n_k^e-1} v_{ik}^e \sum_{j=i+1}^{n_k^e} I_{t-j,k}^e \frac{C_{tk}^e - C_{t-1,k}^e}{C_{t-j,k}^e}$$
(34)

$$D_{tk}^s = \sum_{i=1}^{n_k^s} v_{ik}^s I_{t-i,k}^s \frac{C_{tk}^s}{C_{t-i,k}^s} + \sum_{i=1}^{n_k^s-1} v_{ik}^s \sum_{j=i+1}^{n_k^s} I_{t-j,k}^s \frac{C_{tk}^s - C_{t-1,k}^s}{C_{t-j,k}^s}$$
(35)

$$D_{tk} = D_{tk}^e + D_{tk}^s .$$
(36)

III. ESTIMATES OF ECONOMIC DEPRECIATION AND PROFITS

A. Estimates of Depreciation. Table 1 presents estimates of historical- and current-cost depreciation for 1947-71, prepared according to the preceding formulas. Only the totals for manufacturing as a whole are given; the detailed estimates by industry and by type of asset appear in appendix tables C.1 - C.3 (historical cost) and C.5 - C.7 (current cost). In addition, Table 1 gives the BEA series on capital consumption, which reflects depreciation reported on business income tax returns.

(1) Historical-Cost Estimates. At the beginning of the period, the historical-cost estimates exceed the BEA figures, since many assets acquired during World War II were amortized under emergency provisions enacted during the war. By 1951-52, the two series do not differ significantly; but the combination of accelerated amortization of emergency facilities during and after the Korean War and of accelerated depreciation beginning in 1954 created an excess of tax depreciation charges over historical-cost estimates by about 20 percent. Adoption of the guideline lives in 1962 once again boosted tax depreciation charges, eventually to levels exceeding my estimates by about 45 percent. The impact of the Asset Depreciation Range (ADR) system, adopted in 1971, appears to be rather small, but additional observations are required before conclusive judgments can be drawn.

(2) Current-Cost Estimates. The erratic behavior of the current-cost estimates is striking. The formula used in computing them reveals that the current-year change in prices of new capital goods plays a

Table 1

Comparison of BEA and Coen Estimates of Capital Consumption,

Total Manufacturing, 1947-71
(Billions of Dollars)

Year	BEA	Capital Consumption		Excess of BEA over	
		Historical Cost	Coen	Historical Cost	Coen (percent)
1947	2.418	2.749	10.103	-12.0	-76.1
48	2.855	3.182	5.693	-10.3	-49.8

66	15.584	10.945	15.682	44.9	1.1
67	17.354	12.222	18.898	42.0	- 8.2
68	18.977	13.222	19.409	43.5	- 2.2
69	20.681	14.095	26.356	46.7	-21.5
70	21.714	15.146	29.212	43.4	-25.7
71	23.440	16.037	32.705	46.2	-28.3

crucial role in determining year-to-year changes in the series. Thus, the high rate of inflation immediately following World War II pushed the estimates to levels greatly exceeding both tax allowances and my historical-cost estimates. As the postwar inflation subsided, the excess of current- over historical-cost depreciation diminished although it remained large; however, the Korean inflation once again widened the gap. Moderation of price increases in the 1954 recession, in conjunction with the introduction of accelerated depreciation for tax purposes in that year, brought tax allowances and current-cost depreciation into fairly close alignment, but only until prices began to rebound in the mid-1950's. During the period of sluggish activity and stable prices extending from the late 1950's to the mid-1960's, current-cost depreciation grew slowly (it even fell in two years). As a consequence, tax depreciation actually overtook current-cost depreciation for a few years, and the two figures were nearly identical in 1966. Finally, the inflation commencing in the Vietnam War period again generated very high levels of current-cost depreciation, with tax allowances falling 28 percent below current-cost depreciation by the end of the period.

It is interesting to note the strong countercyclical movements in the current-cost estimates. During periods of rapid economic expansion and high employment, prices rise relatively sharply, thus augmenting the depreciation estimates. The retardation of inflation during recessions generally reverses this effect, although 1971 stands as an important exception. By contrast, the measures based on historical cost display a rather smooth upward trend. Hence, if firms were permitted to depreciate

assets on a current-cost basis similar to the procedure employed here, tax depreciation allowances would become a destabilizing influence on aggregate economic activity. When the economy is booming and prices are rising, the rapid growth in depreciation allowances would reduce business tax liabilities below what they would be under historical-cost accounting. As the economy weakens in recessions, stable or declining prices would reduce current-cost depreciation, and would enlarge tax liabilities to levels above those associated with historical-cost accounting.

(3) Estimates by Industry. The detailed estimates by industry contained in the appendix display widely varying patterns which are difficult to summarize in a few words. Some salient points may be noted, however. My historical-cost estimates exceed tax allowances in 1947 in ten of the 21 industries covered, but the various liberalizations of tax allowances during the 1950's and early 1960's vastly changed the situation. By the mid-1960's, every industry was enjoying tax allowances which exceed my historical-cost estimates, and this relationship persisted through 1971, except in the rubber industry. Two industries - tobacco and non-electrical machinery - appear to be receiving especially favorable treatment in 1971. On the other hand, current-cost depreciation exceeded tax allowances in 1947 in all but two industries - lumber and miscellaneous manufacturing. Liberalization of tax allowances, in conjunction with changes in inflation rates, brought tax allowances into line with current-cost depreciation by the mid-1960's in most industries, the notable exceptions being textiles, paper, rubber, primary metals, transportation equipment, and miscellaneous manufacturing. The high inflation rates

toward the end of the period again lead to substantial excesses of current-cost over tax depreciation in all but two industries - tobacco and non-electrical machinery. Note that the two industries that appear to be most favorably treated in 1971 on the basis of the historical-cost estimates also appear to be most favorably treated on the basis of the current-cost estimates. However, the least favorably treated industry in 1971 in the former case is rubber, while in the latter case it is petroleum.

B. Estimates of Profits. My estimates of historical- and current-cost depreciation can readily be used to derive new estimates of profits in manufacturing industries. In keeping with the BEA profits series to which I wish to compare my own, profits are defined as gross product originating less indirect business taxes, compensation of employees, net interest, and capital consumption allowances. The data used in calculations are those supplied by the BEA, except that I substituted my series on economic depreciation for the BEA series on capital consumption.

Table 2 presents the BEA and my own profits estimates for total manufacturing. Detailed estimates by industry appear in appendix tables D.1 - D.2 (historical cost) and D.3 - D.4 (current cost). Of course, whenever my estimate of economic depreciation exceeds BEA's capital consumption, my profits estimate must lie below BEA's, and conversely. The historical-cost based measures indicate overestimation of profits by BEA by about 2 percent in the period 1947-50, while in 1951-52 our estimates do not differ significantly. Continued liberalization of tax depreciation after 1952 leads to growing underestimation of profits by BEA, with the underestimates reaching about 28 percent by the end of the period. When

I speak of an "underestimate" here, I mean the following: if firms had calculated historical-cost depreciation allowances consistently at rates implied by revealed service lives and depreciation patterns, then (with other things equal) they would have recorded profits 28 percent higher in 1970-71.

A different picture emerges from the current-cost based estimates. In this case the BEA profit series exceeds my own by substantial margins until 1954. The inflationary period in the mid-1950's once again leads to large overestimates of profits by BEA, but from 1958 through 1968 the two series are quite similar. Then with the resumption of high inflation rates in the late 1960's, a sizable gap reappears, with my estimate falling 35 percent below BEA's by 1971.

Since discrepancies between BEA profits and my own estimates simply reflect differences in our measures of depreciation, I shall not comment on the detailed findings by industry.

IV. ECONOMIC DEPRECIATION AND REPLACEMENT REQUIREMENTS

Business firms frequently complain that tax depreciation allowances, which must be calculated at historical cost, do not keep pace with the rising expense of replacing capital goods in times of inflation. Of course, this argument loses some of its force if firms are permitted to write off assets more rapidly than is warranted by actual economic depreciation, even though only the historical cost of the asset can eventually be written off. The purpose of this section is to explore the relationship between replacement requirements valued at current prices and depreciation allowances for tax purposes. Comparisons of replacement requirements with my depreciation estimates are also made.

In my work on investment behavior, I have obtained estimates of replacement requirements which best account for the observed fluctuations in gross capital expenditures in manufacturing industries. To illustrate, let

d_{ik}^e = capacity depreciation (loss of efficiency) of equipment used in industry k in the i-th year after they are acquired.

d_{ik}^s = capacity depreciation (loss of efficiency) of structures used in industry k in the i-th year after they are acquired.

R_{tk}^e = real (constant dollar) replacement requirements for equipment used in industry k in year t.

R_{tk}^s = real replacement requirements for structures used in industry k in year t.

C_{tk}^e = price index of new equipment used in industry k in year t.

$$C_{tk}^S = \text{price index of new structures used in industry } k \text{ in year } t.$$

The capacity depreciation patterns (the d's) were established in my examination of investment behavior [3] and:

$$R_{tk}^e = \sum_{i=0}^{n_k^e} d_{ik}^e \frac{I_{t-i,k}^e}{C_{t-i,k}^e} \quad (37)$$

$$R_{tk}^s = \sum_{i=0}^{n_k^s} d_{ik}^s \frac{I_{t-i,k}^s}{C_{t-i,k}^s} \quad (38)$$

Total replacement requirements valued at current prices are then given by:

$$R_{rk} = C_{tk}^e R_{tk}^e + C_{tk}^s R_{tk}^s, \quad (39)$$

Summing over all 21 industries, we have an estimate of replacement requirements valued at current prices for total manufacturing in year t.

My estimates of current and constant (1958) dollar replacement requirements in total manufacturing for 1948-71 are given in the first two columns of Table 3.^{3/} When the current-dollar estimates are compared with the BEA capital consumption series in column 3, replacement requirements substantially exceed capital consumption for 1948-53. This finding might again be partially explained by amortization of defense facilities during World War II, which tended to depress tax depreciation allowances in the immediate postwar years. From 1954 until 1962, BEA capital consumption was roughly in line with replacement requirements, indicating that the influence of rising capital goods prices on the cost of

70	13.503	17.915	82.5	118.3	61.3
71	13.829	19.357	82.6	120.7	60.3

replacement was offset during this period by the impact of accelerated depreciation on tax write-offs. Liberalization of tax depreciation in 1962 reduced replacement requirements to about 80 percent of tax depreciation charges, a relation that persisted throughout the late 1960's and early 1970's, despite the rapid inflation which characterized these years. Thus, tax depreciation allowances in 1971 were about as generous, relative to replacement requirements, as they have ever been in the post-war period, and the relationship between tax allowances and replacement has not changed much in the last ten years.

The fourth column of Table 3 illustrates the behavior of current-dollar replacement requirements relative to my series on historical-cost depreciation. There is much less variation in this relationship than in the relationship between current-dollar replacement and BEA capital consumption, because my series applies consistent accounting practices throughout the period. However, current-dollar replacement requirements exceed my estimates of historical-cost depreciation in every year, the average excess being around 20 percent.

By contrast, there is a high degree of variation in the relationship between current-dollar replacement requirements and current-cost depreciation as shown in the fifth column of Table 3. Throughout the period, replacement requirements fell short of current-cost depreciation, often by large amounts, although the two are roughly similar in 1949, 1954, 1958, and 1960.

In assessing these empirical findings, one should bear in mind some basic theoretical relationships between replacement and depreciation. First of all, if capital goods prices were constant over time, and if real gross expenditures were growing at a constant rate, then replacement would forever

be less than depreciation. This is because the productive capacity of capital goods declines more slowly than their value, since their value reflects the discounted stream of future net revenues. A light bulb represents an extreme example of this; it loses no productive capacity (generates no replacement requirements) until the final hour of its life, but it loses value (generates depreciation) during each hour of its life. If a firm acquired a constant number of new light bulbs each hour, its replacement requirements and depreciation per hour would eventually be identical; but if it acquired a constantly increasing number of new light bulbs, its depreciation would forever exceed its replacement requirements.

Now suppose that capital goods prices are rising at a constant rate and again consider the extreme case of a light bulb. Current-dollar replacement requirements for a particular bulb will still be zero until the end of its service life. Yet as we have seen above, current-cost depreciation will be greater, relative to the case of no inflation, in each hour of its service life. Hence, inflation, as well as growth in real capital expenditures, can drive a wedge between current-dollar replacement and current-cost depreciation, causing the latter to exceed the former.

If all capital goods were like light bulbs and real capital expenditures were constant over time, then a constant rate of inflation would not cause current-dollar replacement to exceed forever current-cost depreciation, since the total of current-cost depreciation over the life of a bulb is exactly equal to the total of replacement requirements, namely, the cost of replacing the bulb at the end of the service life. If, however, unlike light bulbs, capital goods lose efficiency over their service lives, then the total of current-cost depreciation must exceed the total of current-dollar replacement requirements over the life of each asset: total depreciation equals the

cost of a new asset of the same type at the end of the service life, whereas total replacement can be thought of as the sum of the expenditures required each period to replace a fraction of the asset's productive capacity by purchasing a fraction of a new asset of the same type. Thus, in the case of assets that lose efficiency over their service lives, inflation, even with constant real capital expenditures, will cause current-cost depreciation to exceed forever current-dollar replacement requirements.

In conclusion, it appears that tax depreciation allowances were not large enough to meet replacement requirements in the late 1940's and early 1950's, but they were more than adequate in the 1960's and early 1970's. If firms had instead been required to depreciate assets for tax purposes at historical costs using service lives and depreciation patterns revealed by investment behavior, then throughout the postwar period, tax allowances would not have covered replacement requirements. Finally, if firms had been permitted to adjust consistent historical-cost depreciation to reflect changes in capital goods prices, as in my current-cost measure of depreciation, then tax allowances would have been on the whole extremely generous when viewed relative to current-dollar replacement requirements.

V. ESTIMATES OF GROSS RATES OF RETURN

The measures of economic depreciation of equipment and structures by industry described in Section II may be used to estimate the values of stocks of equipment and structures held by each industry at the end of each year. Let B_{tk}^e and B_{tk}^s denote the book values of equipment and structures, respectively, held by industry k at the end of year t . In the case of historical-cost accounting, we have

$$B_{tk}^e = \sum_{i=0}^{n_k^e} (I_{t-i,k}^e - D_{t-i,k}^e) \quad (40)$$

$$B_{tk}^s = \sum_{i=0}^{n_k^s} (I_{t-i,k}^s - D_{t-i,k}^s), \quad (41)$$

where D^e and D^s are given by previous equations. In the case of current-cost accounting, we have

$$B_{tk}^e = \sum_{i=0}^{n_k^e} [I_{t-i,k}^e \left(\frac{C_{tk}^e}{C_{t-i,k}^e} \right) - D_{t-i,k}^e] \quad (42)$$

$$B_{tk}^s = \sum_{i=0}^{n_k^s} [I_{t-i,k}^s \left(\frac{C_{tk}^s}{C_{t-i,k}^s} \right) - D_{t-i,k}^s]. \quad (43)$$

Adding the value of inventory stocks at the end of each year, we have estimates of total assets, excluding land and any residential structures held by manufacturing concerns.

I have approximated the rate of return on total assets by relating the flow of profits plus net interest during each year to the average of total assets on hand at the beginning and end of the year. The resulting estimates of the rate of return are gross of taxes, and are shown in percentage and index form (1948=100) for total manufacturing in Table 4. Detailed estimates of book values of total assets and rates of return by industry are given in appendix tables E.1-E.2 (historical cost) and E.3-E.4 (current cost). By way of comparison, BEA estimates [4] of the gross rate of return for all nonfinancial corporations are given in percentage and index form in the last two columns of Table 4.

My estimates of the rate of return based on historical-cost accounting are about double those of Gorman in every year. This discrepancy results in part from differences in coverage of the two series, but a more important factor is the difference between historical- and replacement-cost accounting. The historical-cost series also exhibits some striking differences in its movements during the postwar years as compared to Gorman's. While Gorman's estimates never regain or surpass their 1948 peak level, my historical-cost series peaks in 1951 and indicates rates of return in 1965-66 that were roughly the same as in 1948. On the other hand, the two series yield some strikingly similar conclusions. They both fall to their postwar lows in 1970, and the 1970 levels are about the same relative to the 1948 levels. Also, both series indicate that each of the postwar recessions (1954, 1958, and 1971) pulled the rate of return down to a lower level than the preceding recession.

70	16.8	56	9.2	41	9.4	53
71	17.6	59	8.9	40	9.9	56

^a/ Gross rate of return is profits before taxes (excluding inventory valuation adjustment) plus net interest divided by simple average of book value of assets at the beginning and the end of the year.

^b/ From John A. Gorman, "Non-Financial Corporations: New Measures of Output and Input," Survey of Current Business, March 1972, Table 5, pp. 26-27.

It should be noted, however, that while Gorman's results seem to point to a secular decline in the rate of return, the sharp 1965-66 recovery in my historical-cost series casts some doubt on this hypothesis.

The estimates based on current-cost accounting exceed Gorman's estimates (although not by as wide a margin as the historical-cost measures) in all but the last two years. However, they display variations over time that are notably different than both Gorman's estimates and my historical-cost estimates. The current-cost based measure scarcely declines at all in the 1949 recession, and by 1955 it achieves a peak well above the 1948 level. As in the other two series, a trough occurs in 1958, but at a somewhat higher level relative to 1948. Thereafter, the current-cost based rate of return recovers even more dramatically than the historical-cost measure, reaching a peak in 1965 that is 19 percent above the 1948 level. Thereafter, a precipitous decline sets in, carrying the rate of return to a level absolutely lower than Gorman's by 1971. There is even less support in the current-cost estimates for the hypothesis of secular decline in the rate of return.

The detailed results by industry appearing in Tables E.2 and E.4 reveal wide variations among industries as well as over time. Since data on inventories were not available for some industries in selected years (see Table B.3 for the missing observations), rates of return could not be calculated for the entire period in all cases. One curious aspect of the tables is the preponderance of negative rates of return in petroleum. Discussions with Jack Gottsegen of the Commerce Department confirmed my suspicion that the problem is one of industrial classification.

Data supplied by the industry is not adequate to accurately allocate firms' activities between mining and manufacturing, in part because firms follow internal transfer pricing policies that are intended to maximize depletion allowances in their mining operations. Therefore, the petroleum industry is excluded from the following discussion.

In the early years of the postwar period, the historical-cost based rates of return are comparable in most industries to those for manufacturing as a whole. However, rates of return in the furniture, paper, rubber, stone, clay, and glass, and auto industries are significantly above average, while those in textiles and miscellaneous manufacturing are well below average. By 1971, rankings have changed and the amount of variation has also increased.^{4/} Tobacco, lumber, printing and publishing, autos, and instruments record quite high rates relative to the average, while textiles, furniture, paper, rubber, primary metals, and transportation equipment display quite low rates.

Variation in the current-cost measures is somewhat larger in 1953 and much larger in 1971.^{5/} The industries displaying unusually high rates of return in the early part of the period are lumber, paper, rubber, stone, clay, and glass, electrical machinery, and autos, and those with unusually low rates of return are textiles and miscellaneous manufacturing. At the end of the period, tobacco, autos, and instruments show especially high rates of return, while paper, rubber, primary metals, and transportation equipment show especially low ones. Thus, on the basis of either historical- or current-cost accounting, four industries record extraordinary rates of return in the earlier years (paper, rubber, stone,

clay, and glass; and autos), while two industries record extraordinarily low rates - (textiles and miscellaneous manufacturing). By 1971, three industries appear to enjoy exceptionally high rates under either measure (tobacco, autos, and instruments), and four exceptionally low rates (paper, rubber, primary metals, and transportation equipment). The specific characteristics of the 1971 recession no doubt influence the rankings in that year, so one must be cautious in drawing conclusions from these comparisons.

VI. CONCLUSION

It is important to stress once again that the current-cost accounting procedure applied in this study is based on a very special set of assumptions - in brief, that all changes in capital goods prices result from changes in prices of output, that these changes are completely unanticipated, and that price expectations are completely inelastic. I personally consider these assumptions to be rather extreme, and I would regard the current-cost concept employed here as a polar case. It no doubt produces estimates of current-cost depreciation that are more sensitive to price changes than other reasonable alternatives. In the near future I hope to examine some of these alternatives. Until comparative analyses of different concepts are completed, I am reluctant to draw firm conclusions from the present investigation.

TABLE E.4 COEN ESTIMATES OF GROSS RATES OF RETURN BASED ON CURRENT-COST DEPRECIATION, 1947-71

FOOTNOTES

1/ The revealed service lives and depreciation patterns employed here are given in the appendix. They correspond to those reported in [3].

2/ A little algebraic manipulation reveals that nominal income in this case is rC_1 in year 1, rC_2 in year 2, rC_3 in year 3.

3/ Detailed estimates of replacement requirements by industry are not presented in this paper.

4/ The standard deviation of the rates of return is 7.5 percent in 1953, or 29 percent of the mean, versus 10.2 percent in 1971, or 58 percent of the mean. These values exclude petroleum.

5/ For the case of current-cost accounting, the standard deviation of the rates of return is 7.0 percent in 1953, or 34 percent of the mean, versus 11.4 percent in 1971, or 128 percent of the mean.
